Common-Reflection-Surface Stack and conflicting dips

Jürgen Mann, Geophysical Institute, University of Karlsruhe, Germany

Summary

The recently introduced common-reflection-surface (CRS) stack simulates a zero-offset (ZO) section from multi-coverage seismic reflection data for 2-D media in a data-driven way, i.e., without explicit knowledge of the macro-velocity model. The “best” stacking operators are determined by an optimization of the coherency along different test stacking operators in the multi-coverage data. Previous implementations determine only one optimum stacking operator for each ZO sample to be simulated. Consequently, conflicting dips are not taken into account but only the most prominent event contributes to a particular stack sample. This can lead to a lack of coherency of some events in the simulated ZO section. In this work, I show how this limitation can be overcome.

The pragmatic search strategy of the original CRS stack implementation consists of three one-parametric search steps to determine the stacking operators. In the first step, an automatic CMP stack, conflicting dips can hardly be considered because the respective stacking velocities might be quite similar. However, I observe that conflicting dips can still be detected and separated in the subsequent search steps that are applied to the result of the automatic CMP stack.

I propose an extension of the pragmatic approach to account for conflicting dips. For ZO samples where conflicting dips are detected, an additional one-parametric search is required. This provides a set of three kinematic wavefield attributes for each of the conflicting events. Stacking along the respective operator for each particular event allows to simulate their interference in the simulated ZO section by means of superposition.

Introduction

The CRS stack method (Müller, 1998, 1999; Mann et al., 1999; Jäger et al., 2001) simulates a ZO section by summing along stacking surfaces in the multi-coverage data. The stacking operator is an approximation of the kinematic reflection response of a curved interface in a laterally inhomogeneous medium. Three kinematic attributes associated with wavefronts of two hypothetical eigenwave experiments are the parameters of the stacking operator. Coherency analyses along various test stacking operators are performed for each particular ZO sample to be simulated. The stacking operator (and its three associated wavefield attributes) yielding the highest coherency is used to perform the actual stack.

In principle, I have to determine the global maximum and a set of local maxima of the coherency measure in the three-parametric attribute domain. However, even the determination of the global maximum turns out to be too time consuming in a three-parametric search strategy. Therefore, I cannot expect to be able to detect additional local maxima in this way.

Müller (1998) proposed to split the three-parametric problem into three one-parametric searches and an optional three-parametric local optimization as depicted in the simplified flowchart in Figure 1.

The first search step of this pragmatic approach is an automatic CMP stack. The search parameter is the stacking velocity \( v_{NMO} \) which can be written in terms of the CRS wavefield attributes as

\[
\frac{v_{NMO}^2}{t_0} = \frac{2 \nu_0 R_{NIP}}{t_0 \cos^2 \alpha}.
\]

The next two search steps are applied to the CMP stacked section. The search parameters are \( \alpha \) and \( R_N \). The former is then used to calculate \( R_{NIP} \) by means of formula (2).
Common-Reflection-Surface Stack and Conflicting Dips

This three-step strategy has to be modified if conflicting dips are to be correctly taken into account. Unfortunately, in spite of the angle-dependence of $v_{\text{NMO}}$, we cannot rely on the first step to separate events with different emergence angles because the associated stacking velocities might be similar or even identical. Furthermore, the sign of the emergence angle $\alpha$ cannot be determined by means of Equation (2).

However, it is possible to detect events with different emergence angles in the second step in the CMP stacked section, although these have not been correctly taken into account by the preceding automatic CMP stack. This is indicated by Figure 2, which was obtained from a real data example. For a given point in the ZO section to be simulated the coherency values are plotted versus the tested emergence angles. We observe three distinct local maxima which are potential candidates for conflicting dips.

We have computed the “angle spectrum” depicted in Figure 2 for a deep-offshore data set. At the considered ZO location, two diffraction patterns (at $\alpha \approx -30^\circ$ and $\alpha \approx 25^\circ$, respectively) and a weak reflection event (at $\alpha \approx 12^\circ$) intersect each other.

Due to the above observations, the three-step approach can be easily extended such as to detect conflicting events with different emergence angles. However, the calculation of $R_{\text{NIP}}$ from $\alpha$ and $v_{\text{NMO}}$ according to Equation (2) is no longer possible, because, in general, we will detect more than one angle of emergence but only one value for the stacking velocity $v_{\text{NMO}}$. Consequently, the approach has to be adapted to account for this fact. An additional search procedure for each radius of curvature $R_{\text{NIP}}^{i}$, corresponding to each conflicting dip $\alpha^{i}$ becomes necessary.

Unfortunately, $R_{\text{NIP}}^{i}$ can be determined neither in the CMP stacked section nor in the original CMP gathers. According to the stacking operator (1), $R_{\text{NIP}}^{i}$ does not influence in the ZO section ($h = 0$), and in the CMP gather ($x_{m} = x_{b}$), $R_{\text{NIP}}^{i}$ and $\alpha^{i}$ cannot be separated. To solve this problem, we propose to perform the additional search for $R_{\text{NIP}}^{i}$ in another subset of the multi-coverage data, namely the common-shot/common-receiver (CS/CR) gather defined by $|x_{m} - x_{b}| \approx |h|$. A simplified flowchart of this strategy is depicted in Figure 3.

![Fig. 2: Coherency measure plotted versus the tested angles of emergence of the normal ray. Distinct local maxima can be observed, although conflicting dips have not been considered in the preceding step. Two diffraction patterns and a weak reflection event intersect each other.](image)

![Fig. 1: Simplified flowchart of the pragmatic approach according to Müller (1998).](image)

![Fig. 3: Simplified flowchart of the adapted search strategy. The index $i$ denotes the different events detected for one and the same ZO sample.](image)
The steep event in the center of the figures intersects several other events. At the intersection points, at least two different stacking operators (and their associated wavefield attributes) have been determined. This can be seen best in Figure 4b where the difference of the emergence angles for the first two conflicting events is depicted. At locations where only one dip is detected, this dip is also displayed in Figure 4d to preserve the spatial context of the events.

The outlined algorithm always determines a discrete number of conflicting events for each particular ZO location. For this purpose, the angle spectra (similar to the example shown in Figure 2) for each ZO location are analyzed applying user-given absolute and relative coherence thresholds.

The separate handling of a discrete number of events with different dips substantially differs from the familiar dip moveout (DMO) approach: in DMO processing, all potential contributions in a given dip range are summed along a relatively small spatial operator. In contrast, the CRS stack separately fits a large spatial stacking operator to each of the contributing events.

Conclusions

The pragmatic approach of Müller (1998) to perform a ZO simulation by means of the CRS stack method can be adapted to also account for the conflicting dip problem. An additional one-parametric search is required to resolve ambiguities introduced by different events contributing to one and the same ZO sample to be simulated. The first results illustrate the applicability of this approach.

The consideration of conflicting dips is necessary to obtain a more physical simulation of a ZO section: the simulated inter-
Common-Reflection-Surface Stack and Conflicting Dips

ference of intersecting events is closer to the result of an actual ZO measurement.

In addition to the more realistic simulated ZO section, the adapted CRS stack strategy provides three kinematic wavefield attributes for each particular event, even if it intersects one or more other events (or its own bow-tie segments). Subsequent applications of these wavefield attributes (e.g., an inversion of the macro-velocity model, calculation of Fresnel zones and geometrical spreading factors etc.) benefit from this fact, because otherwise the wavefield attributes in the gaps between “broken” event segments would have to be interpolated.
